Assessment of Seedling Rate per Hill for Irrigated Rice in a Wet Sub-Tropical Condition of Bhutan

Ngawang, Chezang Dendup, Sonam Tshomo

ABSTRACT

A field experiment was conducted at the research farm of the Agriculture Research and Development Centre (ARDC) Samtenling in Sarpang district of Bhutan in 2020 to assess the effects of transplanting different numbers of seedlings per hill on grain yield and yield components of rice under irrigated conditions. A widely adopted rice variety, Bhur Kambja-1, was used for the study with one to seven seedlings per hill transplanted at 20×20 cm spacing. The experiment was laid out in a randomized complete block design with three replications. The results of the experiment revealed that the number of seedlings per hill had a significant effect on number of tillers per hill and grain yield. In terms of rice grain yield, a significant difference was observed only between three and seven seedlings per hill with a recorded yield of 3.9 and 2.7 t ha⁻¹, respectively. However, no significant effect was established on other yield components, such as the plant height, panicle length, number of grains per panicle, and unfilled grains per panicle. Therefore, this study recommends transplanting three seedlings hill⁻¹ for cultivation of Bhur Kambja-1 rice variety in the wet-subtropical condition of Bhutan as three seedlings per hill yielded significantly higher productivity and could potentially reduce the seed rate.

Keywords: Bhur Kambja-1; Grain yield; Seedlings hill⁻¹; Rice; Yield components

1. Introduction

Rice (Oryza sativa) is the world’s most important food for some 4 billion people (IRRI, 2019) and more than 90% of rice is produced and consumed in Asia (Global Rice Science Partnership (GRiSP, 2013). In Bhutan rice is the staple food crop, indispensable to Bhutanese culture, tradition, religion, and livelihoods (Ghimiray et al., 2008) which is often equated to food security (Chhogyel, Ghimiray, Wangdue, & Bajgai, 2015). It is grown in a wide range of altitudes, starting from tropical lowlands (150 m) in the south to elevations as high as 2600 m in the north (Ghimiray et al., 2008).

However, the rice sector in Bhutan is challenged by shrinking rice areas, often losing to urbanization and other infrastructural development activities. Fallowing of the wetland is also
one of the prominent reasons for reduced rice production area. Rice area in Bhutan in 2010 was 22,550 hectares while it dwindled to 14,668 hectares in 2019 (RSD, 2019), accounting for about 35% reduction over the 2010-2019 period. Despite these impediments, rice in southern Bhutan is grown annually for food in small pockets mostly applying farmers’ traditional cultivation techniques. One of the prevalent techniques is the use of a thick bunch of seedlings hill$^{-1}$ at planting primarily to save the seedlings from pest damages and also for higher yield under irrigated conditions. It is seen during the field visits that this technique is used in both traditional and improved varieties by the farmers.

According to IRRI (2007), the number of seedlings transplanted hill$^{-1}$ depends on three factors which are the traditional practices of the farmers, quality of seedling, and the price of seed. Hybrid seed, which is costlier, is often transplanted as one seedling hill$^{-1}$ while traditional varieties are sometimes planted with up to six seedlings hill$^{-1}$. In most countries, the farmers plant two to three seedlings per hill (IRRI, 2007). The use of more seedlings hill$^{-1}$ not only adds to cost but is also a waste of natural resources (Saker & Nahar, 2016). Hence, finding a genotype-based appropriate number of seedlings hill$^{-1}$ or planting density is necessary for optimum rice production under limited production resources. The number of seedlings hill$^{-1}$ is an important factor for higher production as it influences the number of tillers, which ultimately determines the yield, because the tillering ability is an inherent trait that varies among rice varieties (Chowhan, Imdadu, Rani, & M., 2019). Hence, extra seedlings are generally desired based on the tillering capacity of the variety and high-tillering rice varieties are desirable for transplanted or direct-seeded rice (De Datta, 1981). However, the use of extra seedlings is an expensive method of ensuring an increased number of tillers (Liu et al., 2021). Therefore, this study was carried out with the objectives to: (a) determine the effect of the number of seedlings hill$^{-1}$ on yield components and grain yield of Bhur Kambja-1, and (b) to recommend the optimum number of seedlings hill$^{-1}$ to the rice farmers of southern Bhutan.

2. Materials and Method

2.1 Experimental site and design

The study was carried out from June to December of 2020 at the research farm of the ARDC-Samtenling, Sarpang Dzongkhag (26° 54’ 17” N latitude and 90° 25’ 51” E longitude) which is located in southern Bhutan. The study site falls under wet-humid sub-tropical agroecology with an elevation of 375 meters above sea level (Figure 1). Treatments included seven different numbers of seedlings viz. 1, 2, 3, 4, 5, 6, or 7 hill$^{-1}$ of popular improved variety of rice in the region (Bhur Kambja-1). The experiment was carried out in a randomized complete block
design with three replications. Each plot size measured 10 m² (5 m × 2 m) and uniform spacing of 20 cm × 20 cm row to plant was maintained for the study. The experimental land was prepared using a tractor and fertilized with urea, single super phosphate (SSP), and muriate of potash (MoP) at the recommended rate of 150, 250, and 50 kg ha⁻¹, respectively. Half dose of nitrogen was applied as basal dose along with full doses of phosphorus and potassium. The remaining half dose of nitrogen was applied in two equal splits at active tillering and panicle initiation stages. Intercultural operations like weeding and irrigation were carried out manually for maintaining the normal growth and development of the crop. And these intercultural operations were uniformly carried out across the seven treatments.

Figure 1. Location of the experimental site in Bhutan

2.2 Data compilation and analysis

Data from the experiment were gathered following the Standard Evaluation System for Rice developed by the International Rice Research Institute (IRRI, 2002) and every care had been taken to minimize errors. The experimental plots were monitored at regular intervals and data for plant height were gathered immediately after flowering, while agronomic parameters such as number of productive tillers, number of filled grains panicle⁻¹, and number of unfilled grains
panicle\(^{-1}\), panicle length, and yields were collected during the harvesting stage as per the methods described by (IRRI, 2002).

The crop was harvested at full maturity and five hills per treatment were randomly selected to gather the required data. All data was collection was performed after discarding two rows of plants from each side of the experimental unit to avoid biases through border effect. The counting of the number of productive tillers, number of filled grains panicle\(^{-1}\) and number of unfilled grains panicle\(^{-1}\) were done manually and panicle length was measured using a scale. The grain yield was determined from the harvested area of 5.04 m\(^2\) adjusting moisture content to 14 % using the standard formula.

\[
\text{Grain yield (t/ha)} = \frac{\text{Adjusted moisture \times Plot yield (kg) \times 10000}}{\text{Plot size \times 1000}}
\]

Where \(\text{Adjusted moisture} = \frac{100 - MC}{100 - 86}\), and \(MC = \text{grain moisture content at harvest}\)

The compilation of data was carried out using Microsoft Excel spreadsheet while analysis of variance (ANOVA) was conducted using statistical software Statistical Tool for Agriculture Research (STAR version 2.0.1) and Statistical Package for the Social Sciences (SPSS version 22). Multiple comparisons among the means were conducted using Tukey’s HSD Test. All effects were declared significant at \(P\)-value \(\leq 0.05\) unless otherwise stated.

3. Results and Discussion

3.1 Plant height

Rice seedlings transplanted with one to seven seedlings hill\(^{-1}\) did not show any significant differences in plant height (\(P\)-value=0.489). The plant heights varied from 98.8 to 103.5 cm, without showing any significant relation to the different seedling rates (Table 1). Though there were no significant differences, transplanting two to three seedlings hill\(^{-1}\) resulted in the numerically tallest plants in this experiment.

Our finding agrees with those of Mahamud, Haque, and Hasanuzzaman (2013) and Faruk, Rahman, and Hasan (2009) who also reported having taller plants when three rice seedlings were transplanted per hill. Plant height is an important trait in rice and has greater bearings on the grain yield and harvest index (IRRI, 2006). The tallest plant height recorded in this study for three seedlings hill\(^{-1}\) is similar to the findings of Faruk et al. (2009), who reported the tallest plant height from two seedlings hill\(^{-1}\) density in BRRI Dhan-33 variety of rice. The Bhutanese
farmers use rice straw as cattle feed, and therefore it is important to assess the optimum seedling rate that will give good grain yield without compromising the straw potential of crop varieties. In an earlier study, the rice variety, Bajo Maap, gave good grain as well as straw yields when transplanted with three to four seedlings hill$^{-1}$ in Wangdi valley of Bhutan (Ghaley, Høgh-Jensen, & Christiansen, 2010).

### 3.2 Panicle length

Panicle length is an important characteristic in rice because together with spikelet number and density, and seed setting rate determines the grain number per panicle which elucidates the productivity or yield in a given situation. The longest panicle was recorded in one seedling hill$^{-1}$ corresponding to 22.5 cm while the shortest was found in the treatment which had three seedlings hill$^{-1}$ (20.8 cm) through the values did not differ significantly (Table 1). A similar finding was also reported by Mahamud et al. (2013) and (Chowhan et al., 2019) who recorded the longest panicle from one seedling hill$^{-1}$. In contrast, Ninad, Bahadur, Hasan, Alam, and Rana (2017) reported the longest panicle length from four seedlings hill$^{-1}$ while they found the shortest panicle length under one seedling hill$^{-1}$ and this could be possibly related to varietal traits. Yao et al. (2015) reported that the panicle length is a quantitative trait controlled by multiple genes which are greatly affected by the environment. However, non-significant differences among treatments could be related to Bhur Kambja-1 and the effect on other varieties may differ.

### 3.3 No. of tillers hill$^{-1}$

Tillering ability is one of the yield-determining parameters in a rice crop and it makes agronomic denotation to evaluate the ability in Bhur Kambja-1. The number of tillers hill$^{-1}$ was significantly affected by seedling rates ($P$-value=0.017). Transplanting of rice at three seedlings hill$^{-1}$ showed the highest number of productive tillers (11). Treatments with one, two and four seedlings hill$^{-1}$ resulted in the lowest number of productive tillers of eight each, whereas the use of five, six and seven seedlings hill$^{-1}$ produced nine tillers hill$^{-1}$ (Table 1).

The significant variation in terms of the tillering ability of Bhur Kambja-1 under different numbers of seedlings at transplantation corroborates the findings of Dejen (2018), Mahamud et al. (2013), Promsomboon et al. (2019), Imran, Inamullah, Naeem, and Khan (2015), and Islam and Salam (2017) who reported significant differences in the number of tillers under different number of seedlings hill$^{-1}$. Tillering capacity may be attributed to the variety and is also affected by cultivation methods such as fertilizer application (Nuruzzaman, Yamamoto,
Nitta, Yoshida, & Miyazaki, 2000). However, Faruk et al. (2009) reported the highest number of tillers from four seedlings hill\(^{-1}\) while Saker and Nahar (2016) reported insignificant differences in tillering due to differences in the number of seedling hill\(^{-1}\), and so the literature needs to be consulted with reference to varieties and crop management practices, not just the number of tillers per hill. In general, high-tillering varieties have a higher number of panicles and thus higher yield in comparison to that of the low-tillering varieties.

### 3.4 Number of filled grains panicle\(^{-1}\)

The result revealed no significant differences in the case of the number of filled grains panicle\(^{-1}\). All the treatments responded with a similar number of filled grains with the highest being 136 filled grains recorded in one seedling hill\(^{-1}\) at transplantation (Table 1). The lowest number of grains was observed for six seedlings hill\(^{-1}\) with only 121 filled grains. This study saw a non-uniform pattern in the number of grains across the treatments with different numbers of seedlings.

Chowhan et al. (2019) reported the maximum number of grains from one seedling hill\(^{-1}\) and their finding is in agreement with our observations. However, the findings of this study are not consistent with the results of Dejen (2018) and Hasanuzzaman, Rahman, Roy, Ahmed, and Zobaer (2009) who found a decreasing trend in the number of grains per panicle with increasing number of seedlings hill\(^{-1}\). This result also disagrees with the finding of Ninad et al. (2017) who reported an increased number of grains panicle\(^{-1}\) with an increase in the number of seedlings hill\(^{-1}\) in rice variety BRRI Dhan-48. Further, the number of grains panicle\(^{-1}\) accounts for higher grain yield (Zhang, Li, Ashraf, Liu, & Li, 2019) while it is determined by panicle architecture like panicle length and length of panicle branch-lets (Kovi, Bai, Mao, & Xing, 2011). Further, the seed setting rate often determines the number of grains panicle\(^{-1}\) which is largely affected by external environment (Zhang et al., 2019). Therefore, the effect of seedlings number in a hill in terms of the number of grains panicle\(^{-1}\) could be location- and genotype-specific under the influence of different environmental conditions. Further, the study showed unfilled grains panicle\(^{-1}\) ranging from 16 to 23 numbers among the treatments. Higher numbers of unfilled grains were observed in six and seven seedlings hill\(^{-1}\) with 23 and 21 unfilled grains, respectively. Thus, as stated by Kobata, Yoshida, Masiko, and Honda (2013) and Fu et al. (2021), halving plant density during flowering increased spikelet fertility by 1.3 to 1.5 times, and therefore use of the right number of seedlings hill\(^{-1}\) is more economic.
3.5 Grain Yield

In terms of rice grain yield, the significant difference (P-value=0.013) was recorded only between three and seven seedlings hill\(^{-1}\) with 3.9 and 2.7 t ha\(^{-1}\), respectively (Table 1). In other words, transplanting with one to seven seedlings hill\(^{-1}\) produces no significant yield differences except for the three seedlings hill\(^{-1}\) treatment.

The lower grain yield in seven seedlings hill\(^{-1}\) may be attributed to lower number of tillers (9) and higher number of unfilled grains (21) (Table 1) in comparison to the three seedlings hill\(^{-1}\) treatment. This is also true for other treatments concerning the number of unfilled grains (17 to 23), but the numbers of tillers hill\(^{-1}\) showed an inconsistent pattern. The maximum grain yield of rice using three seedlings hill\(^{-1}\) was also obtained by Bhowmik, Sarkar, and Zaman (2012) and Dejen (2018). The highest grain yield might be due to optimum density suitable for Bhur Kambja-1 to tiller adequately. A higher number of tillers, especially fertile tillers, was found as the determinant of higher yield in rice (Dejen, 2018; Yumnam et al., 2021). Pruneddu and Spanu (2001) revealed that higher grain yield in hybrid rice was due to a higher number of effective tillers and a higher number of filled grains. However, it must be restated that our findings only represent Bhur Kambja-1 in wet sub-tropics and cannot be generalized to other varieties and locations.

4. Conclusion

Information on seedling rates for all released varieties under the given set of environments is highly useful in exploiting their yield potential. To this end, this is the first study to document the optimum seedling rate hill\(^{-1}\) for a popular rice variety, Bhur Kambja-1 in a field experiment conducted at ARDC Samtenling in Sarpang. The study found that the use of three or four
seedlings hill\(^{-1}\) produced the highest number of productive tillers hill\(^{-1}\), the lowest number of unfilled grains panicle\(^{-1}\), and the highest when planted during the main season under the wet-subtropical condition of Southern Bhutan. This research also shows that the number of seedlings hill\(^{-1}\) did not have significant effects on other yield attributes, such as plant height and the number of filled grains panicle\(^{-1}\). The findings of this study are in agreement with the research conducted earlier, both in Bhutan as well as in other parts of Asia. Thus, this study recommends the use of three seedlings hill\(^{-1}\) for Bhur Khamja-1 rice variety as this seedling rate not only gives the highest grain yield but also could reduce the seed quantity as compared with the more than three seedling hill\(^{-1}\).
